Abstract

1 Introduction

Wikipedia is the largest online encyclopaedia, containing over 5 million pages of content. Moreover, it is one of the most popular websites on the Internet. Wikipedia has a diverse collection of articles from many different topics and is constantly being updated. Although Wikipedia started out as an open platform where anyone could create articles, this led to many factual errors and biased articles. As a result, Wikipedia started to incorporate elements hierarchy gradually over time. In the English version of Wikipedia, all editors require a registered account, and pages that are controversial and of a sensitive nature are protected by administrators.

Administrators are editors who are given access to tools such as blocking and unblocking other users¹, deleting and undeleting pages, protecting and renaming pages etc. Any user can **Request for Adminship** (RfA), an electoral process in which the Wikipedia community participates. The RfA process lasts seven days, during which any editor can comment and discuss the candidate. In their online discussions, editors scrutinize the candidate's contributions and credentials as well as their conduct. They can then state either their support for or opposition to the candidate along with comments. At the end of seven days, a Bureaucrat (an editor higher up in the hierarchy) decides on the "consensus" of the election and declares the outcome. Consensus is not a direct majority voting scheme, and the final judgement rests with the Bureaucrat.

The RfA is a very intense and selective process; there are only 1400 total administrators, of whom only 500 are currently active². This is out of 38 million registered editors with only around 130 000 regular contributors.

This small group of active administrators and editors are responsible for creating and maintaining all articles on Wikipedia.

Therefore, the RfA process can give us valuable insight into the dynamics of social interactions and elections in an online platform. In this paper we will first discuss the existing work on studying the RfA elections and other such similar online processes. Next we provide an overview of the data collected from Wikipedia and how it is used in this paper. We then present our main contribution, the use of a *Viscous Democracy* to model the RfA election process. We discuss the results and possible extensions of this framework to other online elections systems.

2 Literature review

The Wikipedia RfA process has been widely studied in various domains from many different perspectives such as those of the candidate, the voters and the community. In this section we discuss the existing work in this field.

Administrator is a highly coveted status on Wikipedia, and there are many features that can be used to determine the worthiness of a candidate. Wikipedia themselves provide tools and guides³ to help potential candidate assess their own electability. For instance, Wikipedia's *admin score tool* as seen in Figure 1 uses features such as edit counts, pages created, age of account etc. Similarly, Burke et al. [3] utilized data from past RfAs to find features that correlate highly with successful candidates such as presence of edit summaries, politeness in user interactions and varied experience. Such tools and models are useful for finding potential nominees and understanding what the community values and respects. This, however, does not offer any insights into the emergent dynamics

¹the term user and editor can be used interchangeably

²all data as of March 2020 for English version Wikipedia

³<http://en.wikipedia.org/wiki/Wikipedia:GRFA>

in an election.

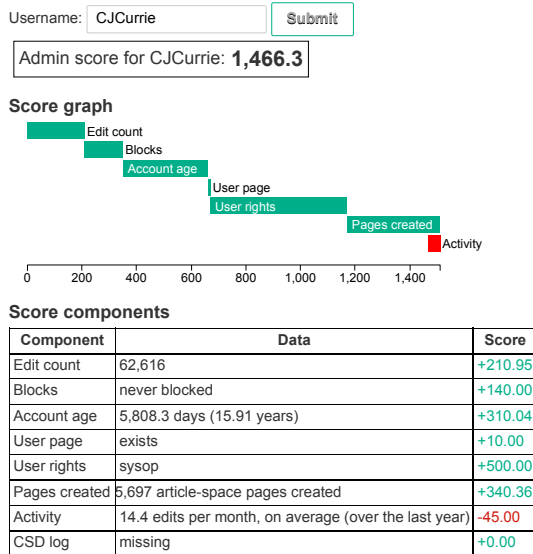

Figure 1: Admin score tool for user CJCurre and its breakdown

Leskovec et al. [12] provide a thorough analysis of the election from the perspective of the voter. They show that the voters make decisions based on *relative assessment* of merit and degree of correspondence with the candidate. Moreover, voters do not follow a *herd mentality* that is usually seen in other information cascade settings. We see an interesting result that voters have diverse personal response functions as well as admin and non-admin patterns of voting differ. Their work presents a detailed picture of the temporal dynamics in a RfA.

As the votes in an RfA election can be positive or negative, they can form a *signed network*, which has been studied and analysed in great detail. For example, Leskovec et al. [13] show that the Wikipedia RfA network is more compliant with status theory compared to balance theory. When they used structural properties of signed networks to predict edges, they observed that the predictive accuracy is poor for the Wikipedia RfA network compared to the other networks in their experiments. However, as signed edge prediction methods are designed to work with any generic signed network, they tend to discard information that RfAs are elections and occur chronologically. There are more works that propose different models and approaches to predicting signed links [1, 10, 7, 5, 16, 4]. Nevertheless, predicting a single edge or a vote in an election does not increase

the accuracy when predicting the result of an election. In this paper, we aim to use the interactions within voters in the Wikipedia network to predict the eventual result of a RfA election.

The work of Desai et al. [6] is related closely with the contributions presented in this paper. Their approach uses linear models for regression and classification to identify a core of *influential voters* through feature selection. Therefore, using a set of 40 most influential voters, they are able to predict the result of an election with high accuracy. They also collect additional network features of the voters independent from the elections. The results do not improve significantly when using these additional features in predicting election results. These results show that there are a group of influential voters that determine election results. This will be more evident when we analyse the dataset in the coming sections.

3 Dataset

We use two different types of data to help build the election model in this paper. The first is information of the votes cast in a RfA and the eventual result of that RfA. This provides us with the users' interactions in an online election process where they have to judge their peers. The second, is information on the interactions of users in other non-elections settings. For example, in Wikipedia, discussions occur in *Talk Pages*. Every type of Wikipedia page (articles, user pages, help pages etc.) includes a corresponding *Talk Page* where users can discuss the contents of that article or interact and provide information to other editors. These data sources will provide valuable details on the activities of editors on Wikipedia.

In this section, we will discuss the existing Wikipedia datasets from Stanford Network Analysis Project (SNAP) [14] that satisfy our requirements and their inherent limitations. Next, we will illustrate the process by which we collected newer data directly from Wikipedia.

3.1 Existing Datasets

For the first type of data, there are two existing Wikipedia RfA datasets in SNAP namely WIKI-ELECT and WIKI-RFA. They both contain the attributes of each vote in a RfA, such as the source, target, vote, timestamp and result of the RfA. The WIKI-RFA is a more recent version of the WIKI-ELECT dataset. It contains RfAs

till May 2013 and also includes the comment text of voters. There are 11 000 users and around 190 000 votes in total present in the WIKI-RfA dataset. Both datasets have been used in many previous works, mostly as signed networks. When we analyse these datasets as vote cast in an election, there are a couple of limitations. More than 5% of WIKI-RfA votes have no timestamp and almost 1% of votes that have no source. As most RfAs have fewer than 300 votes, this is an issue when considering the sequence of votes as well as who has cast a vote.

The interactions between users outside of RfA elections are useful in understanding their behaviour and perceptions of others. Wikipedia users can directly interact with another user by writing on their *User Talk Page*. This can be a measure of how much correspondence exists between two users. This measure provides a good indication of probability of supporting a candidate for an election [12]. The WIKI-TALK dataset on SNAP contains a directed network where an edge from node u to v signifies that u has written in v 's talk page. This dataset is a large network containing more than 2 million nodes and 5 million edges. The limitation of this network data is that nodes do not have user id mappings and the edges are not weighted. Without a node to user id mapping the network cannot be used with the election data. Weighted edges gives the number of times a user has interacted with someone else and is more informative.

Due to the limitations of these existing datasets, we set out to collect our own data to build an election model.

3.2 RfA Data Collection

We parsed through a 60GB XML dump of Wikipedia from Jan 2019 to extract the RfA data. We chose to scrape the data in a format similar to the SNAP WIKI-RfA dataset. The outline of the data extraction process is illustrated in Figure 2. In the first step we filter out all Wiki pages whose title doesn't contain the term `Requests for adminship`. This still leaves us with a lot of non-election Wiki pages, so we can further filter by checking for terms such as `Category:Unsuccessful requests` or `Category:Successful requests`. Now this reduces the our data from over 5 million pages to the roughly 4 000 pages related to RfA elections.

The next step is to process the body of the election pages individually and extract votes from the *Wikitext*, Wikipedia's own markup syntax. After locating the

Support, Oppose and Neutral sections we can extract the individual votes. This step is particularly hard as *Wikitext* syntax changes constantly through the years and there is no fixed page structure. The user's comment can also nested discussion threads which we chose to not extract. Vote comments are terminated with a *signature*, i.e., user id and timestamp. The timestamps also have varied syntaxes adding to the overall complexity of this extraction phase. Using more robust regular expressions to capture multiple timestamp formats and also handling a myriad of edge cases in processing we achieve a much higher coverage of election votes.

We collected 226 781 votes from 4 557 elections with over 13 000 unique user ids. Only 1.6% of votes have missing timestamps and 0.4% have a missing source. We also add a unique id (UID) field to differentiate candidates who had stood for elections multiple times.

3.3 User Interaction Data Collection

Wikipedia has an API to request all the contributions made by a particular user [15]. This offers a rich source of data on the activities of a user on Wikipedia. For instance, in Figure 12 we see the depth of data available for a particular user gathered from the online *editsummary tool*⁴. Therefore, we proceeded to collect the contributions for every unique user in the RfA data querying the API. There are some issues with the user ids that are present in the RfA data. A single user can have multiple aliases and/or change their user id at any point, some users might not have any contributions under an alias that has been discontinued. To simplify our data collection, we assume that each user id is a unique user and fetch all contributions existing under that user id. This resulted in 100GB of data for nearly 11 000 out of 13 000 user ids. We will refer to this dataset `USER-CONTRIB` from this point.

We can see that edits in `USER-CONTRIB` have a *namespace* as seen in Figure 12b. These are categories for each Wiki page, for e.g., `Main` is for all the articles on Wikipedia and `User Talk` is available for each user. Each category also has a the corresponding *Talk Page* for discussions. Therefore, we can get user interactions by looking at the `User Talk` namespace. As an example, in Figure 12d, the top edited user talk page is of `Dianna` (The actual user is `Justlettersandnumbers`, hence the top results are edits on their own page). This allows us to create a dataset similar to the WIKI-TALK dataset, with user id mappings as well as count of number of interactions. The data on top edited pages as seen in

⁴<https://xtools.wmflabs.org/editsummary>

Figure 2: RfA Data Collection Process

Figure 12c can also be used to create a profile of a user’s diversity or speciality of topics.

4 Analysis

In this section, we analyse the datasets and present some general statistics and trends from the datasets described in the previous section.

4.1 RfA statistics

In Figure 13, we see statistics of elections in Wikipedia that show some interesting trends. First, in Figure 13a we see that the average number of votes in elections is increasing with time. This is expected, as initial RfA were just confirmation processes for candidates who were qualified. As the years went by the process starts to get more involved. This is seen in Figure 13c, where there is a peak in the number of successful and unsuccessful elections around 2008 and since then there are fewer election and in total fewer successful ones. A pattern to note: the distribution of votes show that there is a clear majority of support votes in Figure 13b. An interesting fact is that the average number of words in comments seen in Figure 13d show that support votes have much fewer words compared to oppose or neutral votes. This indicates that people who are casting support votes might have small positive comments, while people casting negative or neutral votes tend to write larger comments to convince others of the issues that they find in the candidacy.

4.2 Influential Voters

To find if there is a set of voters in elections who are influential, we utilized two approaches. The first is performing feature selection using a gradient boosting model on the whole dataset as done by Desai et al. [6]. The second approach is similar to finding a set cover.

For the first approach, we created a dataset where each row corresponds to an election and each column is one user. Therefore as we have 4 548 elections and nearly 13 000 users so the data matrix is $X \in \mathbb{R}^{4548 \times 13000}$ and the target is the result of the election, therefore $y_i \in \{1, -1\}$ and $y \in \mathbb{R}^{4548}$. Most users don not vote in

all elections; therefore, the data matrix is very sparse. Unlike Desai et al. [6], we did not fill the unknown votes with 0s, instead we left them as missing values. This is because the XGBoost model is able to handle missing values. After fitting the model with the data we extracted the top 15 features based the *gain* they bring to the model and is shown in Figure 3.

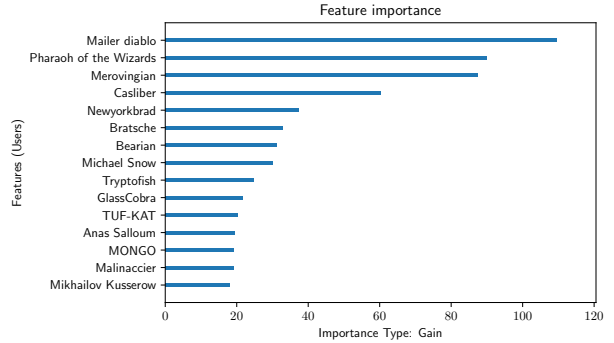

Figure 3: XGBoost feature importance

The second approach was formulating a set cover problem, every element of the ground set is a tuple of (voter, election) and then we create a subset for each unique user. For every user we take each election they participated in and add the people who *follow* that user. A user u is said to follow the user v if u voted after v they and they both voted the same. Therefore the set S_u for every user is defined as

$$S_u = \{(v, e) \mid \text{where } v \text{ voted the same after } u \text{ in election } e\}$$

Then we order the subsets S_u by their size and then try to find how much of the ground set we can cover by taking the top k users’ subsets. The ground set has 221 766 elements, which is fewer than the total number of votes as there are certain elections where either votes were duplicated or people voted twice. Now, we see how the set cover increases as we increase the value of k as shown in Figure 4. We see that with the top 200 users we cover nearly 85% of the whole ground set. With the top 15 users we have 60% coverage. More interestingly, we see that there is a knee around top 25 users and a set cover of 70% indicating that there is a small core of influential users.

Figure 4: Election set cover

Table 1: Top 10 influential users from XGBoost and the Set Cover models

Ranking	XGBoost	Set Cover
1	Mailer diablo	Siva1979
2	Pharaoh of the Wizards	Mailer diablo
3	Merovingian	Newyorkbrad
4	Casliber	Wizardman
5	Newyorkbrad	Pedro
6	Bratsche	Dlohcierekim
7	Bearian	Juliancolton
8	Michael Snow	Casliber
9	Tryptofish	Acalamari
10	GlassCobra	Fastily

In Table 1 we see many common users among the top 10 influential users from both approaches. This confirms the fact that in Wikipedia RfA elections there is a core set of voters who can be important in predicting the result of an election.

5 Viscous Democracy Model

In this section, we explain the concept of viscous democracy [2] and its relevance in decision making on online platforms. We then go on to explain how we can use the concept of viscous democracy to create a model to predict the results of Wikipedia RfA elections.

5.1 Concept

There are three main forms of democracy namely **direct democracy**, **representative democracy**, and **liquid democracy**.

liquid democracy.

Direct democracy is when all the people are involved directly in deciding on any policy. It is the purest form of democracy and can only function well in small social groups, as when the number of people crosses a certain limit it is logistically infeasible to include everyone's opinion. Representative democracy (or indirect democracy) is when people choose a representative who will carry out policy decisions in their favour. This system is widespread in most major countries as well as large social groups. The main drawback of this system of democracy is that the representatives are not obligated to fulfil promises made to the society and once in power can further their self-interest. The representatives also stay in power for a period of time within which the public's stance or view on various policies might change.

Liquid democracy is in-between direct and representative democracy. It is also called **delegative democracy** as people have the chance to delegate their vote to a *proxy* or choose to vote directly. This way the proxy's vote is augmented with all the delegations one receives and can also be transitive in that the proxy can again delegate to another individual. This style of proxy voting works due to **strong transitive delegation**. This means that I am more likely to trust my friend's friend to have similar interest as my own. There is a lot of theoretical and practical research ongoing in this field [11, 9]. The liquid democracy model is not directly suitable for online settings. This is because the social ties online are weak and therefore the transitivity of delegation is weak. It just means that you are less likely to trust your Facebook friend's other Facebook friend.

Therefore, there is a *reluctance* to delegate in online communities. Hence, the weight of the vote attenuates as it is delegated further down a chain. This can be visualized by imagining the the vote that is delegated as viscous and therefore its strength reduces with each additional delegation. This is the main concept behind **viscous democracy**.

Every voting model requires a *ballot* and a *tally* which we will now describe.

5.2 Ballot

A ballot is how a voter expresses their preferences. For instance, in direct and indirect democracy the ballot is usually cast in the form of a vote, either directly for a policy or indirectly for a candidate. The voting system can be a **one person, one vote** system where the voter indicates only one option. Another system is **ranking**

based voting such as Instant-runoff voting (IRV)⁵ or Single Transferable Vote (STV)⁶ where the voter ranks the options in the order of preference. There can also be ballot systems where you rate the options with a numerical score.

For delegative voting systems such as liquid or viscous democracy the choices are to either vote directly or choose to delegate to another person. If we restrict ourselves to only a single vote model then we can consider the ballot as making a *delegation graph* [2]. This concept is illustrated in Figure 5. We assume that we possess an underlying undirected social graph where every node is a person and each edge indicates a connection. For example, the network of friends in Facebook or networks of contact in LinkedIn, etc. Then the delegation graph is built upon the same nodes of the social graph where each node can either vote directly, leading to self loops or choose to delegate to one of their neighbours. Therefore if we assume there is some *delegation rule* that each node follows then the delegation graph is induced from the social graph by applying the rule.

5.3 Tally

The tally is the algorithm that decides the final outcome. In direct or indirect democracies the method of tally might be based on plurality such as **first-past-the-post** or a proportional system where seats or power is awarded to the proportion of the votes received by each candidate.

The tally proposed by Boldi et al. [2] for viscous democracies is a score-based tally where each node in the network receives a score that is calculated based on the delegation graph. This score can then be used along with any requirement such as choosing a committee or one policy out of many alternatives. The method is called *transitive proxy voting with exponential dampening*, where a dampening factor α controls the amount of reluctance in the transitive delegation of votes. They proposed using **Katz’s Centrality index** on the delegation graph. Therefore the score for a node i is defined as

$$\text{Score}_i = \sum_{p \in \text{Path}(-, i)} \alpha^{|p|}.$$

Here, $\text{Path}(-, i)$ is set of all delegation paths ending in node i and $|p|$ is the length of the path [2]. This step is shown in Figure 5, where the *Node Importance Graph* is

⁵https://en.wikipedia.org/wiki/Instant-runoff_voting

⁶https://en.wikipedia.org/wiki/Single_transferable_vote

the delegation graph where each node’s size is proportional to the score that is obtained from Katz’s Centrality with $\alpha = 0.5$. Here we see that the nodes where the delegation chain ends have a larger node score as the votes are transitively transferred.

The parameter $\alpha \in (0, 1)$ acts as the *delegation factor* and $1 - \alpha$ is the *viscosity*. As α approaches 0 the strength of votes delegated tends to 0 hence direct votes have more weight. Therefore, the more viscous the system is the more analogous it is to direct democracy or majority voting. As α approaches 1 almost all the weight of the vote is transferred to the delegate and the node scores correspond to the size of the subtree that they are a part of and the vote and the system is more analogous to liquid democracy [2].

5.4 Model

Now, utilizing all the concepts behind *viscous democracy* we propose a model to predict the Wikipedia RfA elections. This election model also consists of the two parts, namely ballot and tally.

We utilize the interactions between users on Wikipedia to create the underlying **social graph** that is required. Once we have a social graph we use the many features from the user’s contribution data to implement a **delegation rule**. Applying the delegation rule upon the social graph we obtain the delegation graph. Then, choosing an appropriate value of α and applying Katz’s centrality on the delegation graph we obtain scores for each node. We then use the scores to tally votes in an election to predict the result using two approaches.

As we saw in Section 4.2, a small core of voters are important in the result of an election. We can determine these influential voters either on a local scale or a global scale. On a local scale we can choose k most influential voters in an election and then tally their votes to predict the election. We refer to this as the **local tally** approach. Alternatively, we can choose the top k influential voters on a global scale and then only tally their votes in any given election to find the result. We call this the **global tally** approach. Both these approaches aim to use a smaller set of voters to effectively predict the result of an election.

6 Implementation

In this section, we discuss the implementation of various parts the viscous democracy voting model. Firstly, we explain the construction and details of the social

Figure 5: Viscous Democracy Model

Property	Value
Number of Node	12 529
Number of Edges	1 149, 415
Density	0.00732
Largest connected component size	10 565

Table 2: Social Graph properties

graph of Wikipedia editors. Next, we describe the different approaches to form the delegation rule. Lastly, we see the details of the local and global tally methods.

6.1 Social Graph

As described in Section 3.3, the USER-CONTRIB dataset has comprehensive edit history for each user. We use edits from the *User Talk Page* namespace to create an edge in the social graph. The nodes are limited to the users from the RfA dataset so that the size of the graph is not unnecessarily large. An edge exists between user u and user v if u has edited v 's talk page. This provides an underlying directed social interaction graph. The properties of the network are shown in Table 2.

We see that the size of the social graph is smaller than the total number of unique users. This is due to many users changing names or accounts being inactive. The graph is also fairly well connected with a single large connected component and all others are singleton components which correspond to temporary or one-time users. The graph is inherently directed and the successors and predecessors of a node can provide information on whom the node has contacted or who have contacted the node respectively. If we convert the graph into an undirected network the neighbours of a node u are the union of the successors and predecessors. We will use this social graph as the basis of neighbours or contacts for voters in the viscous democracy model.

6.2 Delegation Rule

The most important part of the model is the delegation rule. In their work, Boldi et al. [2] mention that delegation usually happens within the community and that once delegation occurs you can use the viscous democracy to evaluate the scores of each node in the graph. The difficulty is that when using this model to simulate an election we require a heuristic by which people delegate within their neighbourhood. Boldi et al. in their simulation of voting in a co-authorship network used the criteria that a voter would delegate to the person in their neighbourhood who has published more papers, if none exists then they would vote for themselves, choosing not to delegate themselves.

Therefore, in our simulation of Wikipedia RfA elections, we use the attributes of each voter to decide how the delegation would be carried out. We recorded the following information for each node⁷ in the social graph:

1. Start date of the account
2. Total number of edits
3. Ranking

Each of these features results in a different delegation rule which are called **seniority**, **edit count** and **rank** respectively. Given a node u we will define the neighbourhood of the node as \mathcal{N}_u . As mentioned previously the nodes in the neighbourhood depends on whether the graph is directed or undirected. The augmented neighbourhood is defined as appending the node u to the neighbourhood denoted by $\mathcal{N}_u' = \mathcal{N}_u \cup u$. We explain each rule and how it will be applied to the social graph.

⁷the terms node, voter and users can be used interchangeably

6.2.1 Seniority Rule

This rule is based on the start date of each node. The delegation will be done to the node that has the most seniority, i.e., the earliest starting date. If the function $\text{StartDate}(v)$ returns the start date of node v then the delegation function can be written as follows where $\text{delegate}_s(\cdot)$ is the delegation rule based on seniority.

$$\text{delegate}_s(u) = \arg \min_{v \in \mathcal{N}'_u} (\text{StartDate}(v)).$$

This delegation rule is based on the heuristic that people who have been an editor in Wikipedia longer are better placed to make a decision on the administrative qualities of a candidate.

6.2.2 Edit Count Rule

This heuristic is based on the fact that the users on Wikipedia who have more edits are usually more active in the community and are therefore the ones whose votes will be most influential in swaying other voters to support a candidate. Hence given a node u we take the augmented neighbourhood \mathcal{N}'_u and then choose the node which has the highest number of total edits to delegate to. In this way, if there is no neighbour who has more edits than the node u then, the user votes for herself. We define the function $\text{EditCount}(v)$ to return the total number of edits for user v and delegate_E as the delegation function based on edit count. We have

$$\text{delegate}_E(u) = \arg \max_{v \in \mathcal{N}'_u} (\text{EditCount}(v)).$$

6.2.3 Rank Rule

If there exists a hierarchy in the social network then we can use that as a heuristic upon which to delegate votes. It works the same way that the other delegation rules have been defined. Given a node we delegate to the neighbour who has the highest rank, if not then the node votes for herself. This style of voting is particularly useful in societies where there is some organizational structure. However, there is no such defined structural hierarchy amongst Wikipedia editors. Moreover, the administrators themselves are no different than editors with access to tools to help with their roles. Therefore, the first requirement is to find a hierarchy in the directed social graph.

There is already existing work in finding hierarchies in directed networks using concepts such as the concept of *agony* [17, 8]. If each node in a directed graph $G = (V, E)$ is given a ranking, formally defined as $r : V \rightarrow \mathbb{N}$ then any edge $u \rightarrow v$ causes agony if $r(u) \geq r(v)$ and is equal to difference plus one, i.e., $r(u) - r(v) + 1$. The agony of the whole network G with respect to the ranking r is the summation of the agony caused by every edge $e \in E$. The concept of agony is based on the principle that people higher up in a social hierarchy do not prefer to interact with people lower down in the hierarchy. This is the reason why edges $u \rightarrow v$ where $r(u) < r(v)$ causes no agony. Gupte et al. [8] go on to show that the measure of agony of a network corresponds to how close a network is to being a Directed Acyclic Graph (DAG). As DAGs have perfect hierarchies this means that they have a corresponding agony of 0. Therefore, the ranking r is the proposed hierarchy of the network. Gupte et al. provide a method of uncovering this hierarchy in a network by solving the problem of finding the ranking r that minimizes the agony of a network. Tatti [17] provides an algorithm that can solve this problem in polynomial time by solving the dual problem of finding the maximum Eulerian subgraph. We use the algorithm and code of Tatti⁸ to find the ranking for the social graph of Wikipedia editors.

This method of finding the hierarchy penalizes edges from high rank to low rank. This means we must understand the context of a link in the case of the social graph. In the social graph, an edge $u \rightarrow v$ indicates that user u has written in the talk page of v . Therefore, we must ask ourselves if agony occurs when lower ranked users write on higher ranked user pages or if it occurs in the opposite direction. To not restrict ourselves to one approach we computed the rank for both possibilities. In the regular case, this means that agony is caused when high rank users write on low rank user talk pages. The other case is the reversed social graph, where an edge $u \rightarrow v$ means that v has written in talk page of u , and here agony occurs when a lower ranked member writes in a higher ranked user's talk page. We will call the ranks derived from this reversed social graph as *reversed ranks*.

We see the distribution of the ranks in Figure 6 & 7. The number of levels are different with regular ranking having 8 and reversed ranking having 9 levels of hierarchy. In both distributions, we see that the highest level of hierarchy has only around 100 users. This again points to the fact that there exists a small core of influential users in the network based only on their interactions. We can now use the rank that each node had to create two distinct delegation rules.

Given a node u we take the augmented neighbourhood \mathcal{N}_u and then choose the node which has the

⁸<http://users.ics.aalto.fi/ntatti/agony.zip>

largest rank or reversed rank from the set. The functions $\text{Rank}(v)$ and $\text{ReversedRank}(v)$ provide the rank and reversed rank of the node v respectively and the delegation functions $\text{delegate}_R(u)$ and $\text{delegate}_{RR}(u)$ for rank and reversed rank respectively are defined as

$$\text{delegate}_R(u) = \arg \max_{v \in \mathcal{N}'_u} (\text{Rank}(v)).$$

$$\text{delegate}_{RR}(u) = \arg \max_{v \in \mathcal{N}'_u} (\text{ReversedRank}(v)).$$

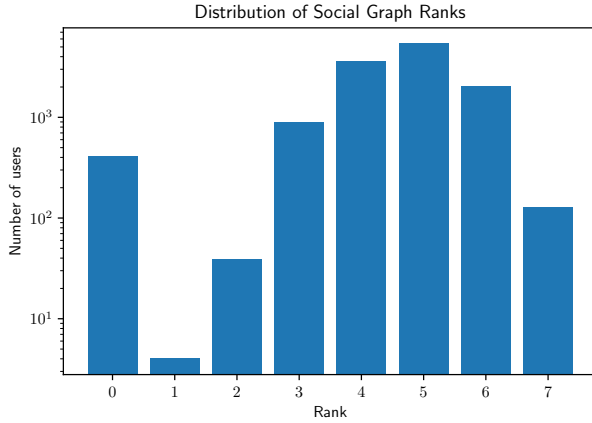

Figure 6: Rank Distribution in Social graph

Figure 7: Rank Distribution in Reversed Social graph

6.3 Tally Schemes

Now, after implementing the social graph of Wikipedia users and simulating the delegation using any one of the delegation rules, we have a delegation graph. From

the delegation graph we can get the node scores by computing Katz's centrality measure with a given value of α . These node scores defined as a function $s : V \rightarrow \mathbb{R}$ can be used to predict elections as discussed in Section 5.3. In both tally approaches we want to select top k users and then predict an election by tallying their votes. This can be either in a global context or a local context. We now describe these two approaches.

6.3.1 Global Tally

In the global context, we take all the nodes of the social graph and then choose k users with the largest scores obtained from the previous steps. Then, we go through each particular RfA and then only take the votes corresponding to the chosen k users and then tally their votes. We then predict the election is successful if there are more support votes, unsuccessful if more oppose than support and a neutral outcome otherwise. This method aims to find a constant core set of influential users obtained from the viscous democracy model. As most users do not vote in every election, we would need a large set of users to have a good predictive accuracy across all the elections in the dataset. As k approaches N , where $N = |V|$ of the social graph, we take all users and their votes in each election to predict the results.

6.3.2 Local Tally

The local context of tallying is when we take an RfA election and then of all the users who voted we choose the k with the largest scores and only tally their votes. We consider a support vote as $+1$, oppose vote as -1 and a neutral vote as 0 . Then the tally of k votes would be the sum of all the k votes. We predict a successful elections if the tally is positive, unsuccessful if the tally is negative and neutral if the tally is exactly 0 . It is evident that in this method that the top k users are not unique and change based on the RfA being predicted. This also means that the size of k could be smaller and might lead to similar and possibly better predictive power compared to the global context.

6.4 Hyperparameters

The viscous democracy model has many parameters and hyperparameters that can be varied. These occur in different stages of the model and affect the final predictive accuracy of the model. In this subsection we will list all these hyperparameters and their possible values.

- α : the delegation factor, $\alpha \in (0, 1)$

- **k** : number of users to consider using node scores, $k \in \mathbb{N}$
- **Delegation Rule**: Seniority, Edit Count, Rank or Reversed Rank
- **Tally Scheme**: Local or Global

We see that there are many possible combinations of parameters and hyperparameters to arrive at a model. In the following section we will present the results of the proposed model.

7 Results and Discussion

In this section, we present the results of the viscous democracy model and analyse the effects of the various parameters on the accuracy of the model.

The main metric we will be using to compare the quality of the Viscous Model is **accuracy**. The baseline that will be used to measure the model against is a simple tally of all the votes in an RfA election. This compares the most directly with our models as we increase the value of k . The baseline model of just tallying the votes gives an accuracy of **82%**.

There are many parameters that have an effect on the predictive accuracy of the model. This means that the effective size of search space is quite large especially as parameters like α have a continuous domain. To narrow the search space as well as to gain a better understanding of the effects each parameter has on the model we fix all others and take a closer look in the following subsections. Finally we discuss the results of the grid search over the pruned parameter space to find the best performing model.

7.1 Effect of α

To study the effects of the delegation parameter α , we need to fix k , the delegation rule and the tally method. As the range of k depends on the tally method, we split these results firstly as either using the GLOBAL VISCOUS or the LOCAL VISCOUS model.

In the GLOBAL VISCOUS model, $k \in [1, 13000]$ and therefore we pick five values of k and plot the accuracy of the model independently using each delegation rule. We see the results in Figure 9. There are some general trends that we can see across all the delegation rules. For small valued of k the quality of predictions are low and as a result the overall accuracy is poor and usually below 50%. This is as expected because in the global tally scheme the top 100 important users might

not vote in all elections, therefore, the model has very few votes to tally in each election. For large values of k such as 8000, we have close to two-thirds of the unique voters and at that point the value of α is irrelevant as the ranking of the top 8000 users changes very little. Moreover, almost all the votes in an election are used to calculate the tally hence the accuracy is constant close to the baseline 80%. For values of k in the middle, we see that as α increases there is a gradual drop in the accuracy. This is clearly seen in the decreasing step-like pattern, for all delegation rules in Figure 9. This indicates that the GLOBAL VISCOUS model is more viscous in nature and works better for smaller values of α .

When we consider the LOCAL VISCOUS model we see that the value of k is bounded by the number of votes in a particular election. Theoretically, we can have a k more than the number of votes in an election, in which case we just choose all the votes to get the tally. The average number of votes in a RfA election is 49 and we chose the following five values $k \in \{5, 10, 20, 40, 80\}$ to analyse. We again see that for $k = 5$ is accuracy is low and for $k = 80$ the accuracy is close to the baseline and is stable. The reasoning is similar to the GLOBAL VISCOUS model, for small k not enough votes and for large k the α does not change ranking enough to affect the top k users. The interesting trend is that unlike the GLOBAL VISCOUS model when we increase k to 20 we see that the LOCAL VISCOUS model actually performs much better than the baseline. This indicates that around the region $k = 20$ there is an additional gain in performance by choosing only the important votes to tally. We also see the general trend that higher values of α tend to decrease the accuracy, especially for the seniority rule as seen in Figure 8. A point to note is that for most values of k and delegation rules the performance drops significantly at the point $\alpha = 0.5$, this indicates there might be a significant change to the ranking of voters in the LOCAL VISCOUS model at this location. Therefore votes in the local model and the global model are **more viscous than liquid**.

7.2 Effect of k

Similar to how we studied the effect of α above, we now take the two tally methods, delegation rules and fixed values of $\alpha \in \{0.2, 0.4, 0.6, 0.8\}$ to understand the effect of the value of k . Though in an indirect way we have analysed this in the previous subsection, we now provide a more detailed view of the trends as well as the ranges to choose for k when later performing the grid search. Again, we will analyse the GLOBAL VISCOUS and

Figure 8: Effect of α for the LOCAL VISCOUS model with different delegation rules and values of k

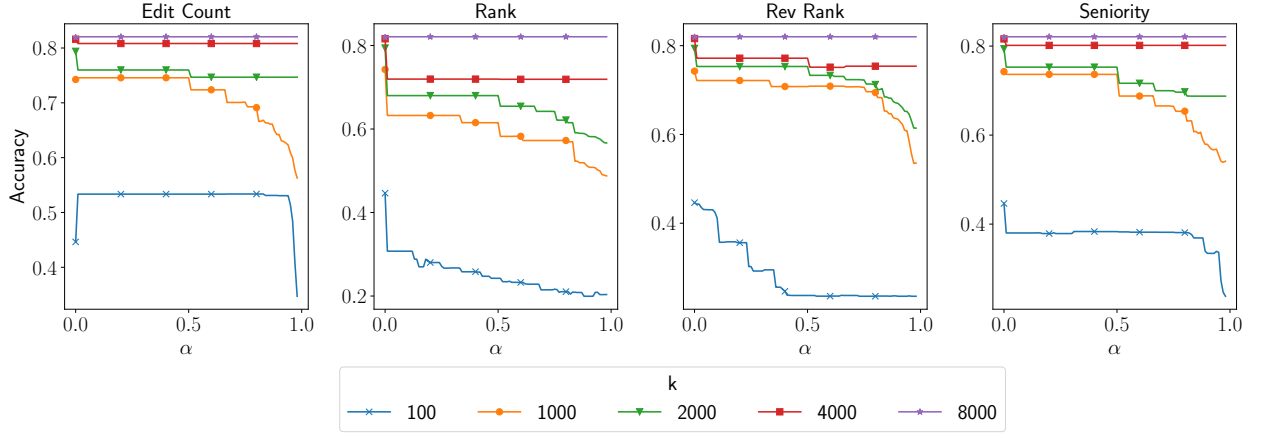

Figure 9: Effect of α for the GLOBAL VISCOUS model with different delegation rules and values of k

LOCAL VISCOUS model separately.

In Figure 11, we see that the GLOBAL VISCOUS model has a knee around $k = 2000$, this is where we see the performance of the model approaching the baseline. It also around this region that the effect of the delegation parameter α is most prominent. In line with our previous analysis, we see that the smaller values of α perform much better than the larger values of α in this region. We can also verify that for both small and large k the change in α has no effect on the accuracy of the model.

We see a similar knee for the LOCAL VISCOUS model in Figure 11. This time it is just before $k = 20$. In this knee region, there are some differences compared to the GLOBAL VISCOUS plots. We see the effect of α is not as pronounced in this region. We also see that there are distinctive spikes that lead to an increase in accuracy before plateauing back to the baseline as k increases.

These spikes confirm the behaviour that we discussed previously in Figure 8. Around this region, the LOCAL VISCOUS model has slightly better performance than the baseline. This is again clearly evident in the $\alpha = 0.4$ line for the seniority delegation rule as shown in Figure 11.

7.3 Grid Search

Gathering all the information from the previous sections on the effects of the parameter α and k , we can narrow down the search space to find the best combination of parameters. As both the LOCAL VISCOUS and GLOBAL VISCOUS models show a tendency to perform better with more viscous votes, we can restrict the search space to $\alpha \in [0.2, 0.45]$. The analysis of the GLOBAL VISCOUS model shows that we need nearly $k = 2500$ to get performance close to the baseline. Correspondingly for the

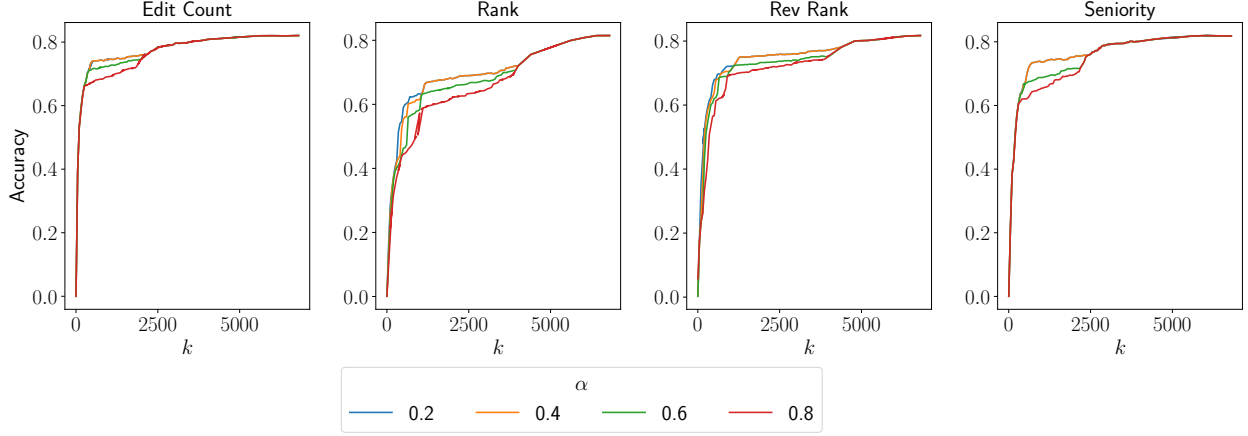

Figure 10: Effect of k for the GLOBAL VISCOUS model with different delegation rules and values of α

Figure 11: Effect of k for the LOCAL VISCOUS model with different delegation rules and values of α

LOCAL VISCOUS model we see for around $k = 20$ we start to get much better accuracy compared to the baseline. Using these as starting points for the grid and random search of the parameter space we obtain the following best combination of model parameters as show in Table 3.

We see that all the LOCAL VISCOUS models have performance greater than the baseline of 82% with the value of k close to 15 most influential users. The value of α indicates that the votes in the network are sufficiently viscous in nature.

8 Conclusions

In this paper we explore the election process for administrator in Wikipedia. We consider the problem of election result prediction using a subset of votes cast.

Table 3: Results of the grid search of the parameters and the model accuracy

Delegation Rule	Tally	k	α	Accuracy
Seniority	Global	≈ 3500	≈ 0.3	0.795
	Local	15	0.303	0.832
Edit Count	Global	≈ 3400	≈ 0.35	0.791
	Local	15	0.346	0.826
Rank	Global	≈ 3500	≈ 0.43	0.794
	Local	17	0.289	0.829
Reversed Rank	Global	≈ 3200	≈ 0.32	0.79
	Local	16	0.298	0.826

We proposed a novel approach to using the theory of viscous democracy to obtain a core set of influential users and predict elections by tallying their votes. This model allows us to understand the nature of election in Wikipedia and the degree of transitive trust present within the network of users. The experimental results show that our model is able to match and also outperform the baseline while only using a subset of the voters.

The small values of the delegation parameter show that the transitive trust in delegating votes is weak and that models with viscous votes perform better. We also see that delegation on the basis of seniority achieves the best performance and indicates that older Wikipedia members wield some influence in administrator elections.

In the future, we would like to create a method to infer the best delegation network and in turn the most optimal delegation rule. Another interesting approach would be to find a model that can explain the behaviour of a voter in a given election that provides a micro viewpoint of the election. This, when combined with the macro viewpoint provided by the viscous democracy model could provide a comprehensive understanding of election dynamics in Wikipedia.
